## Executive Summary

Increasing levels of atmospheric carbon dioxide and other "greenhouse" gases (e.g., methane, chlorofluorocarbons, nitrous oxide) are contributing to an increase in atmospheric temperatures by the trapping of certain wavelengths of heat in the atmosphere. The projected changes in climate will affect human health and well-being through generally warmer temperatures, but also changes in precipitation patterns, rising sea levels and increased storm intensities and frequencies. As over $80 \%$ of the Unites States population resides in urban areas and many greenhouse gas emissions emanate from urban areas, managing urban areas to mitigate emissions and create resilient cities, given these projected changes, is of paramount importance.

One important attribute in urban areas that can both affect emissions and climate change impacts are urban forests. In 2010, U.S. urban areas occupied 27.4 million hectares (ha) - or $3.6 \%$ of land area of the conterminous U.S. — and are projected to increase to 66.0 million ha ( $8.6 \%$ ) by 2060. Given that, on average, trees cover $39.4 \%$ of urban areas in the U.S., current urban tree cover equates to 10.8 million ha and will increase substantially in the coming years. These trees sequester carbon, but also alter building energy use, which consequently affects emissions from power plants. In addition, these trees alter air temperature and reduce storm water runoff, which can mitigate some of the projected impacts from climate change.

The purpose of this report is to aid in understanding the future impacts of urban forests on climate change mitigation at the county level across the conterminous U.S. This report combines projected changes (2010 to 2060) in urbanization and associated urban tree cover to better understand urban forest impacts related to climate changes.

The report estimates projected changes in urban forests related to carbon storage, building energy use and power plant emissions. Two types of projections were developed: Part 1 addresses projected changes in these effects given projected urban growth; Part 2 projects changes only within existing urban areas (no urban expansion).

## Projected Changes to Urban Forest Services Given Projected Urban Expansion

As urban forests and urban populations expand across the nation, urban forests will become increasingly valuable. Between 2010 and 2060, urban land in the conterminous U.S. is projected to grow by 38.5 million ha, with urban tree cover increasing by 10.8 million ha, doubling total urban tree cover to 21.6 million ha. While the amount of urban tree cover will increase as urban land expands, the average percent tree cover in urban is projected to decline from $39.4 \%$ in 2010 to $32.8 \%$ in 2060. This decline in percent tree cover is largely attributed to tree cover changes in areas of urban expansion and the recent trend in loss of urban tree cover and increase in impervious cover, which is projected to continue into the future.

Overall, total urban forest carbon storage value is projected to increase by $\$ 175$ billion; energy conservation by $\$ 3.3$ billion/year; and avoided pollutant emissions by $\$ 1$ billion/year (Table 1).

Table 1. Summary of projected changes in urban area and forest values due to projected urban expansion. Results by county and state are detailed in Part 1 of the report.

| Urban Attribute | 2010 | 2060 | Change |
| :--- | :---: | :---: | :---: |
| Land area (ha) | 27.5 million | 66.0 million | +38.5 million |
| Tree cover (ha) | 10.8 million | 21.6 million | +10.8 million |
| Tree cover (\%) | 39.4 | 32.8 | -6.6 |
| Carbon storage (tonnes) | 852 million | 1.78 billion | +931 million |
| Carbon storage (\$) | 160 billion | 335 billion | +175 billion |
| Energy conservation (\$) | 4.1 billion | 7.4 billion | +3.3 billion |
| Avoided carbon emissions (t) | 6.1 million | 10.3 million | +4.2 million |
| Avoided total emissions (\$) | 1.4 billion | 2.5 billion | +1.0 billion |

While urban forest carbon storage values will increase substantially, much of this increased value is due to conversion from rural forest storage. Thus, overall carbon storage in rural forests will decrease as urban areas expand, with urban forests gaining some carbon storage from the previously rural land. In addition, while savings from energy use and associated emissions will increase due to increased urban tree cover, overall energy use and emissions will increase as urban areas expand.

Efforts to sustain percent tree cover in urban areas at current levels (39.4\%) as urban areas expand are projected to require an annual planting of 25 million trees per year in urban areas, or about one new tree planted annually for every 2.0 ha ( 4.9 acres) of urban land. Sustaining current percent urban tree cover would retain 353 million tonnes of carbon storage, avoid the emission of an additional 3.3 million tonnes of carbon per year, save an additional $\$ 1.9$ billion in energy costs per year, and avoid pollutant emissions with an associated value of $\$ 729$ million per year in the year 2060. Sustaining
tree cover through time sustains multi-billion dollars in benefits annually that are otherwise projected to be lost by 2060 in urban areas as urban land expands. These values are conservative as numerous other benefits are not considered (e.g., air pollution removal, air temperature reduction, human health benefits). However, many rural forest values (e.g., carbon storage, timber production, wildlife habitat) will be lost due to urban expansion. Thus, the expansion of urban forests is likely not a net gain in overall forest values for the nation, but rather just a conversion of forests and other land from rural to urban as population expands. This conversion will likely lead to net loss in total forest values as overall forest cover will likely decline; in addition, emissions from urban areas will increase. More research is needed regarding the locally specific drivers and outcomes of changes in tree cover among rural and urban areas as urban areas expand. The information can be used to help develop specific management and policy actions to sustain tree cover and ecosystem services at desired levels.

## Projected Changes to Urban Forest Services in Existing Urban Areas

Given recent losses in urban tree cover in many areas, tree cover within existing urban areas is projected to decline in the coming years. Loss of urban trees is due to many reasons, including urban development (removal of healthy trees), storms, insects and diseases and old age (attrition). A net loss in tree cover indicates that the loss of existing tree canopies is greater than new canopy cover generated through tree growth, natural regeneration and tree planting. Between 2010 and 2060, urban tree cover in existing urban areas (2010) is projected to decrease $39.4 \%$ in 2010 to $31.0 \%$ in 2060. Overall, total urban forest carbon storage value is projected to decrease by $\$ 34$ billion; energy conservation by $\$ 855$ million/year; and avoided pollutant emissions by $\$ 318$ million/year (Table 2).

Table 2. Summary of projected changes in urban area and forest values within existing urban areas. Results by county and state are detailed in Part 2 of the report.

| Urban Attribute | 2010 | 2060 | Change |
| :--- | :---: | :---: | :---: |
| Tree cover (ha) | 10.8 million | 8.5 million | -2.3 million |
| Tree cover (\%) | 39.4 | 31.1 | -8.3 |
| Carbon storage (tonnes) | 852 million | 671 million | -180 million |
| Carbon storage (\$) | 160 billion | 126 billion | -34 billion |
| Energy conservation (\$) | 4.1 billion | 3.3 billion | -855 million |
| Avoided carbon emissions (t) | 6.1 million | 4.7 million | -1.4 million |
| Avoided total emissions (\$) | 1.4 billion | 1.1 billion | -318 million |

To sustain urban tree cover through 2060, on average, 23 million trees would need to be planted annually. On average, this planting equates to a national rate of one new tree annually for every 1.2 ha ( 3.0 acres) of urban land. Planting 23 million trees per year also equates to each urban resident planting one tree every 11.5 years, or about seven trees during their lifetime, to sustain tree cover in existing urban areas. By reducing projected tree losses (i.e., enhancing preservation of existing canopy),
fewer trees would need to be planted to sustain tree cover. Canopy preservation is often a better option to sustain tree cover than planting as existing trees are already established and larger than planted trees. Sustaining current percent tree cover will prevent these losses by sustaining an additional 180 million tonnes of carbon storage and avoiding the emission of an additional 1.4 million tonnes of carbon (Table 2). Additional urban forest values (e.g., air pollution removal, air temperature reduction, human health benefits) would also be sustained.

## Projection Limitations

The projected changes in urban forest ecosystem services are uncertain, with uncertainty increasing as one projects farther into the future. As these projections are often based on current trends, numerous factors in the future could change these projections (e.g., environmental changes, economic changes, urban forest management and urban development policies and patterns). However, the projections illustrate potential changes in urban forest cover and associated ecosystem services given current patterns of change.

As projections are based on recent trends, some estimates are likely overestimates (e.g., loss of urban tree cover in Central Plains states). All estimates will be subject to fluctuations due to numerous factors. As the environment changes so will the forces that affect urban forest health and productivity. Some factors will enhance, and others will decrease health and productivity. In context with the limitations, projected changes can be used as a starting point for discussion on where to direct policies and management to protect future urban forests and populations. Human decisions related to implementing policies and management actions will ultimately guide urban forest change in the coming years.

## 1. Introduction

This report is Part 1 of a two-part report. Part 1 is designed to aid in understanding the future impacts of urban forests on climate change mitigation given projected future urban expansion. This part only addresses the impacts within urban areas as they expand and does not address the concomitant changes that will occur in rural land as rural lands decrease in area. Part 2 is designed to aid in understanding the future impacts of urban forests on climate change mitigation with no urban expansion. Results are projected at the county level across the conterminous United States for the years 2010, 2030 and 2060. This report does not investigate the impact of climate change on urban forests, rather it investigates how projected urban development will affect future urban tree cover and urban forest impacts on greenhouse gases (Part 1), as well as how projected changes in tree cover in existing urban areas will affect greenhouse gases (Part 2).

Urban forests are defined as all trees within urban areas, from individual trees (e.g., on front lawns) to trees embedded in natural forest stands. The term urban tree cover refers to the canopy cover produced by urban forests.

Urban land is delimited based on U.S. Census Bureau definitions (U.S. Census Bureau 2020). Urban areas (Figure 1) represent densely developed territory and encompass residential, commercial and other non-residential urban land uses. For the 2010 Census, an urban area is composed of a densely settled core of census tracts and/or census blocks that meet minimum population density requirements, along with adjacent territory containing non-residential urban land uses, as well as territory with low population density included to link outlying densely settled territory with the densely settled core. To qualify as an urban area, the territory identified according to criteria must encompass at least 2,500 people, at least 1,500 of which reside outside institutional group quarters. The Census Bureau identifies two types of urban areas:

- Urbanized Areas (UAs) of 50,000 or more people;
- Urban Clusters (UCs) of at least 2,500 and less than 50,000 people.

Figure 1. Urban land and community boundaries in Connecticut.

This report projects urban development and tree cover change in urban areas through 2060, and its associated impacts on carbon storage, building energy use and associated carbon emissions from building energy use. Changes (2010-2030; 2010-2060) within urban areas are assessed for each county. Three future scenarios are assessed:

1. Current Trend - tree cover change based on projected urban growth.
2. Conserve Canopy - similar to current trend projections, but percent urban tree cover held to a minimum of the 2010 percent tree cover value.
3. Enhance Canopy - similar to conserve canopy projections, but also includes a $10 \%$ relative increase in tree cover.

Results in the report are presented within tables and maps. Methods for each projection will be discussed first, followed by resulting tables and maps illustrating variations in these themes across the conterminous U.S.

## 2. Methods

### 2.1. Projected Urban Development and Tree and Impervious Cover

Urban expansion in the U.S. was projected for 2010-2060, based on the average growth within county urbanization classes between 1990 and 2010. Methods and results of these methods are given in Nowak and Greenfield (2018b). For each decade, the amount of urban land at the start of the decade, and new urban land added during the decade, was calculated for each county. The 2010 starting percent urban tree cover was estimated using NLCD tree cover maps (MRLC 2020) for: a) urban land (2000) remaining urban land (2010); and b) rural land (2000) converting to urban land (2010).

As NLCD tree cover is known to underestimate actual tree cover (Nowak and Greenfield 2010), photo-interpretation was conducted to help determine actual tree cover values. State urban tree cover values were determined through photo-interpretation of 1,000 points per state using c. 2014 aerial photos (Nowak and Greenfield 2018a). Urban tree cover estimates for 2010 were adjusted based on ratio of the state average urban tree cover to the estimated urban tree cover based on photointerpretation:

County Urban Tree Cover $=$ county urban tree cover $($ NLCD 2011) $x$ state urban photo-interpreted tree cover c. 2014 (\%) / state urban NLCD tree cover (\%)

It is important to note that just because rural land converts to urban land, not all the land cover will change (e.g., to developed land cover). Urban conversion indicates an increase in population density and development but does not necessarily lead to a complete land cover conversion to developed land. For example, on average, about $20 \%$ of forest land remains as forest when rural land converts to urban land (Nowak and Walton 2005).

To project urban tree cover for each decade (2020-2060), the percent urban tree cover at the start of the decade in each county was adjusted by the projected average annual relative percent change in urban tree cover from the associated state average (c. 2009-2014) (Nowak and Greenfield 2018a). For example, if state urban tree cover changed from $50 \%$ to $49 \%$ between 2009 and 2014, that would equate to a $1 \%$ drop over 5 years, or $-0.2 \%$ per year. The $-0.2 \%$ annual change was converted to a relative change based on the starting tree cover percentage (e.g., $-0.2 / 50=-0.004 \%$ change per relative to existing tree cover). This relative change value was applied to the tree cover from the previous year to project tree cover annually (e.g., tree cover in county in $2010=40 \% ; 2011=(40 \% \mathrm{x}-0.004)+$ $40 \%=39.8 \% ; 2012=(39.8 \% \mathrm{x}-0.004)+39.8 \%=39.7 \%, \ldots)$. The new percent tree cover was applied to urban land remaining urban at the end of the decade to estimate total tree cover in this area.

Total tree cover within urban expansion areas was based on the county-specific percent tree cover from the rural to urban land conversion (2000-2010) multiplied by the land area of urban expansion. The proportion of tree cover in urban expansion areas among NLCD land cover classes was also recorded. Total decadal urban tree cover (2020-2060) was calculated by adding total tree cover in urban land remaining urban and rural land converting to urban land at the end of each decade. For counties with no urban land in 2010, but with urban land in future years, estimates of percent urban tree cover in future years $(2030,2060)$ were derived from the neighboring county with the closest county geographic center to existing county center. Urban impervious cover was also projected using similar methods as for tree cover. Impervious cover projections are needed to assess future potential plantable spaces.

Urban population data by county for 2010 were derived from U.S. Census Bureau (2020). Urban population estimates for 2030 and 2060 were derived from U.S. Forest Service Resources Planning Act (RPA) socioeconomic projections ${ }^{1}$ (Wear and Prestemon 2019; https://www.fs.usda.gov/rds/ archive/catalog/RDS-2019-0041). The RPA projected total county population. To estimate urban populations, the percent of the county's population that was urban in 2010 was applied to future total county populations. This process will likely underestimate future urban populations as the percent urban population is likely to increase in the coming years. Various climate change scenarios were projected in the RPA, but this project used a middle of the road projection of the SSP2 scenario (https://www.fs. usda.gov/rds/archive/catalog/RDS-2018-0014).

### 2.2. Projected Urban Forest Impacts on Reducing Greenhouse Gas Emissions

Urban forests can affect atmospheric carbon dioxide by:

- Sequestering atmospheric carbon as the tree grows
- Emitting carbon as a tree decomposes
- Altering building energy use and consequent carbon and other emissions from power plants

[^0]In addition, trees reduce air temperatures through tree shade and transpiration, and this cooling can offset some of the projected temperature increases in urban areas. While temperature effects are not estimated in this project, tree cover can be used as a proxy for temperature effects (i.e., areas with greater percent tree cover will likely have relatively lower air temperatures). Tree shade and temperature reduction can also have direct effects on building energy use and consequently carbon emissions from energy production. Shade effects from trees will vary depending on tree size and position around a building with tree shade due to leaves and branches often increasing building energy use during heating seasons (Nowak et al. 2014). The effects of tree shade on energy use are relatively greater on smaller residential buildings than larger downtown buildings.

### 2.2.1. Carbon Storage and Sequestration

Projected decadal urban tree cover $\left(\mathrm{m}^{2}\right)$ was converted to total carbon storage and net annual sequestration based on national urban forest carbon storage values ( $7.69 \mathrm{kgC} / \mathrm{m}^{2}$ tree cover) and state specific net sequestration values (Nowak et al. 2013). Net sequestration values are based on estimated gross sequestration due to tree growth minus an estimated loss of carbon due to decomposition from tree death and decay. Net sequestration rates vary depending upon land use and tree health. Based on field data assessments from several cities, the average net sequestration rate averages $74 \%$ of the gross sequestration rate (Nowak et al. 2013).

### 2.2.2. Building Energy Use and Altered Power Plant Emissions

Projected decadal urban tree cover $\left(\mathrm{m}^{2}\right)$ was converted to estimated changes in building energy use and avoided power plant emissions based on methods detailed in Nowak et al. (2017). These methods combined field data on urban trees with local urban/community tree and land cover maps, modeling of tree effects on building energy use and pollutant emissions, and state energy and pollutant costs to estimate tree effects on building energy use and associated pollutant emissions at the state to national level in the conterminous U.S. Avoided emissions were estimated for carbon dioxide $\left(\mathrm{CO}_{2}\right)$, nitrogen oxides $\left(\mathrm{NO}_{\mathrm{x}}\right)$, sulfur dioxide $\left(\mathrm{SO}_{2}\right)$, volatile organic compounds (VOCs), and particulate matter less than 2.5 microns $\left(\mathrm{PM}_{2.5}\right)$. State specific values of energy changes and avoided emissions per $\mathrm{m}^{2}$ of tree cover by NLCD land cover class were applied to decadal urban tree cover estimates by NLCD class within urban areas to derived county estimates. Energy and emission values were based on 2018 values. Emissions are reported as the sum value for all avoided emissions. Emissions values are detailed in Nowak et al. (2017) with the exception that the values for avoided $\mathrm{NO}_{2}, \mathrm{SO}_{2}$ and $\mathrm{PM}_{2.5}$ were based on average county health values per tonne of pollution as derived from BenMAP analyses as detailed in Nowak et al. (2014).

### 2.3. Projection Scenarios

Three county-based projections (2010-2060) of urban forest impacts on carbon storage, building energy use and power plant emissions were conducted:

1. Current trend - estimates based on projected trends of increasing urban development and overall urban tree cover.
2. Conserve Canopy - although urban forest area will expand in extent due to urban expansion, percent tree cover within urban areas is projected to decline. This scenario holds percent urban tree cover in the current trend analysis at a minimum of the 2010 percent tree cover value for each decade.
3. Enhance Canopy - similar to the conserve canopy projections but includes a $10 \%$ relative increase in tree cover over the 2010 percent tree cover values.

### 2.3.1. Current Trend Projections

This scenario projects changes in tree cover and urban forest impacts based on projected urban expansion as described in sections 2.1. and 2.2. This current trend projection is reported for years 2030 and 2060. Subsequent projections of conserved and enhanced canopy are reported for year 2060 as a comparison of change among projections.

### 2.3.2. Conserve Canopy Projections

This scenario was designed to simulate maintaining, through canopy preservation, a minimum of the 2010 percent tree cover in urban areas of each county through the years. In this scenario, if percent urban tree cover in any year dropped below the starting percent tree cover value in 2010, it was assumed that canopy preservation or tree establishment would occur to prevent this potential loss. However, as percent tree cover could increase, when increases in percent tree cover did occur, they were retained. Thus, percent tree cover in each year could exceed the 2010 minimum but could not be lower than this minimum value. Hectares of tree cover needing to be conserved for each county was calculated and converted to number of trees needing to be conserved or established based on an average tree density of 511 trees per hectare of urban tree cover (Nowak and Greenfield 2018b).

### 2.3.3. Enhance Canopy Projections

This scenario builds upon the Conserve Canopy scenario of maintaining a base minimum percent urban tree cover and assumes a long-term tree canopy goal of an additional $10 \%$ tree cover above the base minimum. This $10 \%$ increase is a relative increase, such that if the base minimum tree cover was $50 \%$, the canopy goal would be increased to $55 \%$ (a $10 \%$ increase).

As tree cover varies by regional conditions, so should canopy enhancement rates based on regional environmental conditions. Urban tree cover is highest in forested regions, followed by grasslands and deserts, mainly due to variations in precipitation and seed sources (Nowak and Greenfield 2018b, 2020). To determine the average percent urban tree cover and percent plantable space within U.S. biomes (Table 1), each county was classified as either forest, grassland or desert based on global biome maps (Bailey 1995; Olson and Dinerstein 2002; Nature Conservancy 2018). Percent potentially plantable space was calculated as $100 \%$ minus percent tree cover minus percent impervious cover (i.e., land area that is not covered by trees or impervious surfaces).

The proportion of plantable space needing to be planted to increase tree cover by $10 \%$ for each biome was calculated as: TC x $0.1 /$ PS x 100 , where $\mathrm{TC}=$ percent tree cover and PS in percent plantable space in ecoregion (Table 1). This establishment of new tree cover within potentially plantable areas distributes more tree cover in areas where trees can be more readily established (i.e., forest areas) and minimizes new tree establishment in more water constrained areas (i.e., grassland and desert areas).

The proportion of plantable space in each county was multiplied by the corresponding \%plant (Table 1) to estimate the hectares of new tree cover needed to increase tree cover by $10 \%$.

Table 1. U.S. urban forest cover information by biome.
\(\left.\begin{array}{|l|c|c|c|c|}\hline Biome \& \begin{array}{c}\% of total US <br>

urban area\end{array} \& Tree cover^{\mathrm{b}}\end{array} $$
\begin{array}{c}\text { Plantable }_{\text {space }^{\mathrm{c}}}\end{array}
$$\right]\)| \% plant ${ }^{\mathrm{d}}$ |
| :---: |
| Desert |
| Forest |
| Grassland |
| U.S. Average |

" conterminous United States
${ }^{6}$ average percent tree cover in biome (c. 2014)
' average percent plantable space in biome (c. 2014)
"percent of plantable space needing to be planted to increase tree cover by 10\%

To create a sustainable canopy, this new desired tree cover was not all added in one year but was distributed and added in equal increments over a 50 -year period to prevent large even-aged tree cover additions. For each year, the additional amount of new plantable space created by urban expansion from the previous year was also multiplied by the corresponding \%plant (Table 1) and distributed over a 50 -year period.

Although the average increase in tree cover among all counties was $10 \%$, the actual increase in tree cover was actually $6.7 \%$ nationally ( $2010=39.4 \%$ tree cover; $2060=42.0 \%$ ) due to variability among counties in tree cover, urban growth and county size. Because of distributing the desired additional tree cover over a 50 -year period, an actual $10 \%$ increase in cover will not be attained by 2060, as new cover will continue to be added after 2060. In the long run with sustained additions of new tree cover (\%plant in Table 1), a $10 \%$ increase would be attained. Estimated increases in tree cover varied from $0.2 \%$ to $57 \%$ among counties (average $=10 \%$ ), with a weighted national average of $6.7 \%$. This new tree establishment assumes that the 2010 tree cover percentage is conserved and that the new additional tree cover added annually is also conserved through time. Hectares of new tree cover added each year by county was converted to number of trees needing to be added based on an average tree density of 511 trees per hectare of urban tree cover ${ }^{2}$ (Nowak and Greenfield 2018b). Even though percent tree cover varies among biomes, tree density values per unit of tree cover standardizes the values per unit tree cover. Tree density numbers will vary locally based on local conditions.

For all scenarios, the changes in projected urban tree cover were used to project changes in carbon storage and sequestration as detailed in section 2.2.1. For building energy and avoided emission estimates, changes in urban cover were distributed proportionally among tree cover in NLCD classes to estimate annual tree cover in each NLCD class. These new tree cover estimates were used to estimate energy changes and avoided emissions as detailed in section 2.2.2.

## 3. Results / Discussion

This section displays the results as maps, as well as in tables, for state averages and results for the top 10 and bottom 10 counties relative to the changes in 2060 . Note that these projections are based on the assumptions detailed in the methods and are not projections of what will happen, but rather projections of what would happen if the assumptions and trends in the methods hold true. The farther out one projects into the future, the more unlikely that these trends will hold true. However, while the absolute values of change are likely inaccurate over a 50 -year projection, the data reveal probable areas of greatest change in the coming years. The projections and trends may change in the future if various policies or other factors change (e.g., economic depression) that would alter future conditions. To that end, by understanding projected changes, management and policies, actions could be implemented to direct the future to the most desirable outcomes.

### 3.1. Projected Urban Development and Tree Cover

### 3.1.1. Urban Population

Assuming no increase in the proportion of urban population in counties, the urban population in the conterminous U.S. is projected to increase by 91 million by 2060 , increasing from 247.5 million (2010, Figure 2) to 338.4 million (2060). States with the greatest urban population increase are Texas, California and Florida (Table 2). Counties with the greatest urban population increase are Maricopa County, Ariz. (Phoenix area), Harris County, Texas (Houston area) and Clark County, Nev. (Las Vegas area) (Table 3; Figure 3).

| State | Population $\Delta$ |
| :--- | :---: |
| Texas | $14,823,000$ |
| California | $13,318,000$ |
| Florida | $10,995,000$ |
| Georgia | $4,806,000$ |
| Arizona | $4,202,000$ |
| North Carolina | $3,004,000$ |
| Colorado | $2,835,000$ |
| Virginia | $2,834,000$ |
| Washington | $2,757,000$ |

Table 2. Projected change ( $\Delta$ ) in urban population (2010-2060) by state.

[^1]| State | Population $\Delta$ |
| :---: | :---: |
| Nevada | 2,675,000 |

### 3.1.2. Urban Land

Urban land in the conterminous U.S. is projected to increase by 38.5 million ha (5.0\%) by 2060, increasing from 27.4 million ha $(3.6 \%, 2010$, Figure 4$)$ to 66.0 million ha $(8.6 \%, 2060)$ (Nowak and Greenfield 2018b). States with the greatest projected increase in percent urban land are Rhode Island, Delaware and Connecticut (Table 4). Counties with the greatest increase in percent urban land are Jefferson Parish, La. (near New Orleans), Lake County, Ind. (Gary, Ind. area) and Rockdale County, Ga. (near Atlanta) (Table 5; Figure 5).

| State | Urban land $\Delta$ (\%) |
| :---: | :---: |

[^2]
### 3.1.3. Percent Urban Tree Cover

While urban land is projected to expand in the coming decades, the percent urban tree cover is projected to decrease by $5.8 \%$ by 2060, decreasing from $39.4 \%$ (2010, Figure 6) to $33.6 \%$ (2060). Tree cover gained through urban expansion is expected to some of the projected tree cover loss in existing urban areas (see Part 2), but this urban tree cover gain comes from previously rural tree cover (thus, rural lands are losing tree cover). States with the greatest projected decrease in percent urban tree cover are Kansas, Oklahoma and Iowa (Table 6). Many states in the Central plains are projected to lose urban tree cover as these states exhibited recent tree cover loss (c. 2009-2014; Nowak and Greenfield 2018a) and urban expansion is limited within forested areas, which will limit the amount of new existing forest tree cover that is subsumed by urban expansion. Recent trends of tree cover change influence the projections (i.e., areas losing tree cover will continue to lose tree cover), but these recent trends may change in the coming years due changes in policies related to tree protection, new tree plantings and/or natural regeneration changes.

Counties with the greatest decrease in percent urban tree cover are Clayton, Iowa (near Dubuque), McCurtain, Okla. (southeastern Oklahoma) and Ohio, West Virginia (Wheeling, W.Va.) (Table 7; Figure 7). Kansas and Oklahoma had the greatest projected reduction in tree cover. The relatively high loss in Kansas is due mainly to urban expansion while the loss in Oklahoma is also influenced by relatively high recent tree cover losses that are projected into the future. Oklahoma has the most counties in the top 10 with the greatest percent reduction in tree cover. This magnitude of tree cover is likely an overestimate as the current loss in cover will likely not be sustained in the coming decades. This same issue likely holds for other counties with substantial (e.g., $>10 \%$ ) loss in urban tree cover, but these counties are under considerable threat for tree cover loss given current trends.

| State | Tree cover $\Delta$ (\%) |
| :--- | :---: |
| Kansas | -19.2 |
| Oklahoma | -16.8 |
| Iowa | -16.4 |

### 3.2. Projected Changes in Urban Forest Ecosystem Services and Values

The changes in extent of urban land (i.e., urban expansion) and changes in tree cover within urban areas will directly affect the ecosystem services and values of the urban forest in the future. That is, the amount of future urban tree cover is a main driver of future ecosystem services and values in, and around, urban areas. The actual rate of ecosystem services per unit tree cover will likely change in the future as species composition and environmental conditions change. Many of these future changes are unknown as not only does the environment change urban forests, but so do human actions. Many natural projections of change may be altered by human actions. For example, while species compositions are projected to change (e.g., Iverson and Prasad 2001), management in urban areas may accelerate or diminish the change based on tree planting and removals. Projections do not account for policy changes that could affect tree cover (e.g., large tree planting campaigns) or various forces that could devastate the local urban forest (e.g., hurricanes, insect or disease outbreaks).

Given that urban land is projected to increase and percent tree cover with urban areas is projected to decline, on average approximately 26 million additional new trees will need to be established annually to account for the loss of tree cover and keep percent urban tree cover at current levels in 2060 nationally. In addition, the tree cover that remained during this time also needs to be sustained. Assuming a nominal $1 \%$ mortality rate of the base tree cover that remained during this time period, an additional 47 million trees will need to be established annually to sustain the base tree cover. Thus, a total of approximately 73 million trees would need to be established each year to sustain urban tree cover. As about two-thirds of existing trees come from natural regeneration (Nowak 2012), annual tree planting nationally would need to be about 24 million trees to sustain current percent tree cover levels from 2010 to 2060 given current urban tree cover projections. On average, this planting equates to a national rate of one new tree planted annually for every 2.0 hectares ( 5.0 acres ) of urban land. To enhance tree cover by $10 \%$, an average of an additional 19 million trees would need to be established annually.

In the future, climate change could affect carbon storage and sequestration rates, but there are various counter-indications as to what might happen to carbon storage and sequestration. While climate change effects of increased $\mathrm{CO}_{2}$ and longer growing seasons will increase growth rates (e.g., Taub 2010, Deryng et al. 2016) and potentially stand densities (Devi et al. 2020), decreasing wood densities (Pretzsch et al. 2018) and possible decreased life spans due to increased growth rates when young (Büntgen et al. 2019) may offset carbon gains of increased growth. Given the uncertainties of future carbon densities per $\mathrm{m}^{2}$ of tree cover, projections of urban forest carbon effects use current carbon storage and sequestration densities.

### 3.2.1. Carbon Storage and Value

Carbon storage values are related to tree species, sizes and densities, while annual carbon sequestration relates these same factors plus annual growth and mortality rates. Carbon storage is estimated based on the national average carbon storage density ( $\mathrm{kgC} / \mathrm{m}^{2}$ tree cover) from several U.S. cities. Gross carbon sequestration ( $\mathrm{kgC} / \mathrm{m}^{2}$ tree cover/yr) is based on state-specific growth rates and average tree
competition and conditions as derived from the sample of U.S. cities. Net sequestration accounts for carbon losses due to mortality and tree decomposition and are estimated as $74 \%$ of gross sequestration (Nowak et al. 2013).

Carbon storage in U.S. urban forests is projected to increase by 975 million tonnes ( $+114 \%$ ) by 2060, increasing from 852 million tonnes (2010, Figure 8) to 1.83 billion tonnes (2060). Given the 2020 value of the social cost of carbon ( $\$ 188 / \mathrm{tC}$ in 2018 dollars; Interagency Working Group on Social Cost of Carbon 2016), the carbon storage value of the urban forest will increase by $\$ 183$ billion by 2060, increasing from $\$ 160$ billion (2010) to $\$ 343$ billion (2060). This increase in carbon storage is due to the expansion of urban land. While urban forest storage will increase, carbon storage in rural forests will decrease as there will be less rural forest land. On average, only about $14 \%$ of urban lands contain forested stands (Nowak et al. 2013). Thus, as rural forested areas convert to urban land, they will lose a large proportion of their forest extent and, thus, associated carbon storage.

States with the greatest projected increase in urban forest carbon storage are Florida, California and North Carolina (Table 8). Counties with the greatest increase in urban forest carbon storage are Worchester County, Mass. and San Bernardino and Los Angeles counties, Calif. (Table 9; Figure 9).

| State | Storage $\Delta(\mathrm{t})$ |

### 3.2.1.1. Projected Changes in Carbon Storage with Conserved or Enhanced Canopy

The projections in section 3.2.1 are based on current projections of urban expansion and tree cover change. Other scenarios were developed based on conserving or enhancing tree cover. Relative to the current declining tree cover projection, conserving tree cover at its current percent tree cover would add an additional 314 million tonnes of carbon storage ( $\$ 59.0$ billion) by 2060 ; enhancing urban tree cover by 2060 would add an additional 462 million tonnes of carbon storage ( $\$ 86.8$ billion) (Table 12).

Table 12. Amounts and differences (million tonnes) in 2060 carbon storage and annual carbon sequestration (seq.) based on current projected trends, canopy conservation and canopy enhancement scenarios.

| Scenario | Storage | Diffa $^{\text {a }}$ | SEQ. | Diff $^{\text {a }}$ |
| :--- | :---: | :---: | :---: | :---: |
| Trend | $1,826.8$ | na | 73.3 | na |
| Conserve | $2,140.5$ | 313.8 | 85.7 | 12.4 |
| Enhance | $2,288.7$ | 461.9 | 91.6 | 18.3 |

a difference from trend scenario
na - not applicable

States with the greatest increase in carbon storage due to the conservation or enhancement of current percent tree cover are Texas, Georgia and Illinois (Table 13). State with the greatest increase in annual carbon sequestration in 2060 with canopy conservation and enhancement are Texas, Georgia and Tennessee (Table 14). Counties that have the greatest increases in carbon storage and sequestration from canopy conservation or enhancement tend to be in Arizona, Oklahoma and Texas (Tables 15-16).

Table 13. Differences in 2060 state carbon storage (tonnes) for conserve canopy and enhance canopy scenarios vs. the current trend scenario.

| State | Conserve $^{\text {a }}$ | State | Enhance $^{\text {b }}$ |

### 3.2.2. Building Energy Conservation

Building energy conservation values are related to average tree distributions around buildings among land cover classes and changes in land cover distribution and tree cover with land cover classes (Nowak et al. 2017). The values are also related to state-specific energy costs and types of energy used to heat and cool buildings, as well regionally specific tree cover effects on building energy use depending on tree size and orientation around a building. As urban areas increase, total building energy use will increase. On average, urban trees reduce building energy use by $7.2 \%$ (Nowak and Greenfield 2017). Thus, as building energy use will increase with urban expansion, so will energy conservation values due to trees around buildings.

Projections of tree effects on building energy use assume that energy costs and fuel types stay consistent in the future (2030 and 2060). In reality, energy types and distributions will likely change in the future as energy efficiencies and building designs change. Energy costs are also likely to increase in the coming years.
U.S. urban forests are projected to reduce building energy costs by an additional $\$ 3.5$ billion/year by 2060, with savings increasing from $\$ 4.1$ billion/yr (2010, Figure 12) to $\$ 7.7$ billion/yr (2060). This increase in energy savings is due to the expansion of urban land. While urban forests will save energy, overall energy costs will increase as urban land expands. States with the greatest projected increase in energy savings are California, Florida and Massachusetts (Table 17). Counties with the greatest projected increase in energy savings are Riverside and San Bernardino in southern California and Maricopa, Ariz. (Table 18; Figure 13).

### 3.2.2.1. Projected Changes in Energy Conservation with Conserved or Enhanced Canopy

The projections in section 3.2.2 are based on current projections of urban expansion and tree cover change. Other scenarios were developed based on conserving or enhancing tree cover. Relative to the current national trend of declining percent tree cover, conserving tree cover at its current percent tree cover would save an additional $\$ 1.6$ billion in energy costs in 2060; enhancing urban tree cover by 2060 would save an additional $\$ 2.3$ billion per year (Table 19).

Table 19. Amounts and differences (million \$) in 2060 energy savings based on current projected trends, canopy conservation and canopy enhancement scenarios.

| Scenario | Energy Savings (\$) | Diff $^{\text {a }}$ |
| :--- | :---: | :---: |
| Trend | 7,676 | na |
| Conserve | 9,248 | 1,572 |
| Enhance | 9,952 | 2,276 |

a difference from trend scenario
na - not applicable

States with the greatest increase in energy savings due to the conservation or enhancement of current percent tree cover are Texas, Arizona and Illinois (Table 20). Counties that have the greatest energy savings from canopy conservation or enhancement tend to be in Arizona, Kansas and Texas (Table 21).

### 3.2.3. Avoided Emissions

The projected changes in building energy use will alter emissions from the sources of fuels used to produce the energy. State or national emission factors and costs by fuel type were used to estimate changes in emissions due to changes in building energy use (Nowak et al. 2017). The emission factors and costs from 2010 were held constant for the years 2030 and 2060.
U.S. urban forests are projected to reduce emissions due to reduced building energy use by an additional value of $\$ 1.1$ billion/year by 2060, with emission reduction values increasing from $\$ 1.4$ billion/yr (2010, Figure 14) to $\$ 2.6$ billion/yr (2060). Carbon emissions from energy production will be reduced by an additional 4.7 million tonnes per year by 2060, increasing avoided emissions from 6.1 million $\mathrm{tC} / \mathrm{yr}$ (2010) to 10.8 million $\mathrm{tC} / \mathrm{yr}$ (2060). This increased reduction in emissions is due to the expansion of urban land and urban forests. While urban forests will reduce emissions, overall emissions will increase as urban land expands. States with the greatest projected reduction in carbon emissions are Michigan, Florida and Pennsylvania (Table 22). States with the greatest value from reduced emissions $\left(\mathrm{CO}_{2}, \mathrm{NO}_{x^{2}}, \mathrm{SO}_{2}, \mathrm{CO}, \mathrm{CH}_{4}, \mathrm{VOCs}, \mathrm{PM}_{10}\right.$ and $\left.\mathrm{PM}_{2.5}\right)$ are Florida, California and Michigan (Table 23). Counties with the greatest reduction in carbon emissions are Maricopa County, Ariz., Worchester County, Mass.; and Riverside County, Calif. (Table 24; Figure 15). Counties with the greatest reduction in total avoided emissions are Riverside and San Bernardino counties in southern California and Maricopa County, Ariz. (Table 25; Figure 16).

### 3.2.3.1. Projected Changes in Avoided Emissions with Conserved or Enhanced Canopy

The projections in section 3.2.3 are based on current projections of urban expansion and tree cover change. Other scenarios were developed based on conserving or enhancing tree cover. Relative to the current declining tree cover projection, conserving tree cover at its current percent tree cover would avoid the emission of an additional 2.8 million tonnes of carbon by 2060 and avoid pollutant emissions with an associated cost of $\$ 615$ million per year. Enhancing urban tree cover by 2060 would avoid the emission of an additional 3.9 million tonnes of carbon by 2060 and avoid pollutant emissions with an associated cost of $\$ 875$ million per year (Table 26).

Table 26. Amounts and differences in 2060 avoided annual carbon emissions and total value from reduced annual pollutant emissions based on current projected trends, canopy conservation and canopy enhancement scenarios.

| Scenario | Carbon $^{2}$ | Diff $^{b}$ | Emission $^{\text {c }}$ | Diff $^{\text {b }}$ |
| :--- | :---: | :---: | :---: | :---: |
| Trend | 10.7 | na | 2,587 | na |
| Conserve | 13.6 | 2.8 | 3,202 | 615 |
| Enhance | 14.7 | 3.9 | 3,462 | 875 |

${ }^{\text {a }}$ million tonnes of avoided carbon emissions
${ }^{6}$ difference from trend scenario
${ }^{\prime}$ annual value (million \$) from reduced $\mathrm{CO}_{2}, \mathrm{NO}_{2}, \mathrm{SO}_{2}, \mathrm{CO}, \mathrm{CH}_{4}, V O C s, P M_{10}$ and $\mathrm{PM}_{2.5}$ emissions
na - not applicable

States with the greatest increase in avoided carbon emissions and reduced pollutant emission environmental costs in 2060, due to the conservation or enhancement of current percent tree cover, are Illinois, Kansas, Texas and Ohio (Table 27-28). Counties that have the greatest increase in avoided carbon emissions from canopy conservation or enhancement tend to be in Arizona, Kansas and Illinois (Tables 29). Counties that have the greatest reduction in pollutant emission costs from canopy conservation or enhancement tend to be in Arizona, Kansas, Illinois and Texas (Tables 30).

## 1. Introduction

This report is Part 2 of a two-part report. Part 1 is designed to aid in understanding the future impacts of urban forests on climate change mitigation given projected future urban expansion. Part 2 is designed to aid in understanding the future impacts of urban forests on climate change mitigation with no urban expansion. Results are projected at the county level across the conterminous United States for the years 2010 and 2060.

This report projects tree cover change in urban areas through 2060, and its associated impacts on carbon storage, building energy use and associated carbon emissions from building energy use. Changes (2010-2030; 2010-2060) within urban areas are assessed for each county. Three future scenarios are assessed:

1. Current Trend - tree cover change based on projected urban growth.
2. Conserve Canopy - similar to current trend projections, but percent urban tree cover held to a minimum of the 2010 percent tree cover value.
3. Enhance Canopy - similar to conserve canopy projections, but also includes a $10 \%$ relative increase in tree cover.

Results in the report are presented within tables. Methods for each projection will be discussed first, followed by resulting tables illustrating variations in these themes across the conterminous U.S. The results are based on extrapolating recent percent urban tree cover changes among states (c. 2009-2014) (Nowak and Greenfield, 2018a). As most states had declining percent tree cover in urban areas, these losses are projected to continue in the future. There are numerous reasons why these recent trends could change (e.g., changes in policies, tree planting, storms, insects and diseases, development), but these results illustrate the potential change if the reason tree cover changes continue into the future. These projections are not indications of what will happen, but rather projections of what would happen if the current trends hold true.

## 2. Methods

### 2.1. Projected Changes in Urban Tree Cover

Projected tree cover changes were estimated using urban tree cover change data from c. 2009-2014 (Nowak and Greenfield 2018a). Average annual percent change in state tree cover change was used to project annual tree cover changes for each county with the state. For example, if state urban tree cover changed from $50 \%$ to $49 \%$ between 2009 and 2014, that would equate to a $1 \%$ drop over 5 years, or $-0.2 \%$ per year. The $-0.2 \%$ annual change was converted to a relative change based on the starting tree cover percentage (e.g., $-0.2 / 50=-0.004 \%$ change per relative to existing tree cover). This relative change value was applied to the tree cover from the previous year to project tree cover annually (e.g., tree cover in county in $2010=40 \% ; 2011=(40 \% \mathrm{x}-0.004)+40 \%=39.8 \% ; 2012=(39.8 \% \mathrm{x}$ $-0.004)+39.8 \%=39.7 \%, \ldots 2060=32.7 \%)$.

### 2.2. Carbon Storage and Sequestration

Projected decadal urban tree cover $\left(\mathrm{m}^{2}\right)$ was converted to total carbon storage and net annual sequestration based on national urban forest carbon storage values ( $7.69 \mathrm{kgC} / \mathrm{m}^{2}$ tree cover) and state specific net sequestration values (Nowak et al. 2013). Net sequestration values are based on estimated gross sequestration due to tree growth minus an estimated loss of carbon due to decomposition from tree death and decay. Net sequestration rates vary depending upon land use and tree health. Based on field data assessments from several cities, the average net sequestration rate averages $74 \%$ of the gross sequestration rate (Nowak et al. 2013).

### 2.3. Building Energy Use and Altered Power Plant Emissions

Projected decadal urban tree cover $\left(\mathrm{m}^{2}\right)$ was converted to estimated changes in building energy use and avoided power plant emissions based on methods detailed in Nowak et al. (2017). These methods combined field data on urban trees with local urban/community tree and land cover maps, modeling of tree effects on building energy use and pollutant emissions, and state energy and pollutant costs to estimate tree effects on building energy use and associated pollutant emissions at the state to national level in the conterminous U.S. Avoided emissions were estimated for carbon dioxide $\left(\mathrm{CO}_{2}\right)$, nitrogen oxides $\left(\mathrm{NO}_{\mathbf{x}}\right)$, sulfur dioxide $\left(\mathrm{SO}_{2}\right)$, carbon monoxide $(\mathrm{CO})$, methane $\left(\mathrm{CH}_{4}\right)$, volatile organic compounds (VOCs), and particulate matter less than 10 microns ( $\mathrm{PM}_{10}$ ) and less than 2.5 microns $\left(\mathrm{PM}_{2.5}\right)$. State-specific values of energy changes and avoided emissions per m 2 of tree cover by NLCD land cover class were applied to decadal urban tree cover estimates by NLCD class within urban areas to derived county estimates. Energy and emission values were based on 2018 values. Emissions are reported as the sum value for all avoided emissions. Emissions values are detailed in Nowak et al. (2017) with the exception that the values for avoided $\mathrm{NO}_{2}, \mathrm{SO}_{2}$ and $\mathrm{PM}_{2.5}$ were based on average county health values per tonne of pollution as derived from BenMAP analyses as detailed in Nowak et al. (2014).

### 2.4. Projection Scenarios

Three projections (2010-2060) of urban forest impacts on carbon storage, building energy use and power plant emissions were conducted:

1. Current trend - a base projection based on recent trends in tree cover change
2. Conserve Canopy - this scenario holds percent urban tree cover at a minimum of 2010 percent tree cover value
3. Enhance Canopy - similar to conserve canopy projections, but includes a $10 \%$ relative increase in tree cover (e.g., 2010 tree cover $=50 \%, 2060$ tree cover $=55 \%$ )

For all scenarios, the changes in projected urban tree cover were used to project changes in carbon storage and sequestration, building energy savings and avoided emission estimates. That is, the changes in these ecosystem services and values are proportional to the changes in urban tree cover.

## 3. Results / Discussion

This section displays tables of state averages, as well as tables for the top 10 and bottom 10 counties relative to the changes in 2060. Note that these projections are based on the assumptions detailed in the methods and are not projections of what will happen, but rather projections of what would happen if the assumptions and trends in the methods hold true. The farther one projects into the future, the more unlikely that these trends will hold true. However, while the absolute values of change are likely inaccurate over a 50 -year projection, the data reveal probable areas of greatest change in the coming years. The projections and trends may change in the future if various policies change or other factors change (e.g., economic depression) that would alter future conditions. To that end, by understanding projected changes, management and policies, actions could be implemented to direct the future to the most desirable outcomes.

### 3.1. Urban Tree Cover

The percent urban tree cover in existing urban areas is projected to decrease by $8.3 \%$ by 2060 , decreasing from $39.4 \%$ (2010) to $31.1 \%$ (2060). States with the greatest projected decrease in percent urban tree cover are Oklahoma, Georgia and Tennessee (Table 1). Oklahoma is projected to lose the greatest percent urban tree cover as this state exhibited the highest recent tree cover loss (c. 20092014; Nowak and Greenfield 2018a). Projected trends may change in the coming years due to changes in policies related to tree protection, new tree plantings and/or natural regeneration changes.

Counties with the greatest decrease in percent urban tree cover were all in Oklahoma, while counties with the greatest projected increase were all in Wyoming. These patterns are directly related to the average state changes between c. 2009-2014. This magnitude of tree cover change in these states are likely an overestimate as the current change in cover will likely not be sustained in the coming decades.

| State | Tree cover $\Delta$ (\%) |
| :---: | :---: |
| Oklahoma | -20.6 |
| Georgia | -16.7 |
| Tennessee | -15.5 |
| Arkansas | -15.1 |
| Rhode Island | -15.0 |
| Montana | -14.6 |
| Oregon | -14.5 |
| Alabama | -14.3 |

| South Dakota | 4.4 |
| Wyoming | 8.6 |

### 3.2. Projected Changes in Urban Forest Ecosystem Services and Values

The changes in urban tree cover will directly affect the ecosystem services and values of the urban forest in the future. That is, the amount of future urban tree cover is a main driver of future ecosystem services and values. The actual rate of ecosystem services per unit tree cover will likely change in the future as species composition and environmental conditions change. Many of these future changes are unknown as not only does the environment change urban forests, but so do human actions. Many natural projections of change may be altered by human actions. For example, while species compositions may be projected to change, management in urban areas may accelerate or diminish the change based on tree planting and removals. Projections do not account for future policy changes that could affect tree cover (e.g., large tree planting campaigns) or various forces that could devastate the local urban forest (e.g., hurricanes, insect or disease outbreaks).

Given a projected loss of 2.3 million hectares of tree cover between 2010 and 2060, and an average 511 trees per hectare of tree cover (Nowak and Greenfield 2018b), approximately 24 million trees would need to be established annually to account for tree cover loss. In addition, the tree cover that remained during this time period also needs to be sustained. Assuming a nominal $1 \%$ mortality rate,
an additional 45 million trees are likely established annually to sustain the base tree cover. Thus, a total of approximately 69 million trees would need to be established each year to sustain urban tree cover. As about two-thirds of existing trees come from natural regeneration (Nowak 2012), annual tree planting nationally would need to be about 23 million trees to sustain current percent tree cover levels from 2010 to 2060, given current urban tree cover projections. On average, this planting equates to a national rate of one new tree planted annually for every 1.2 hectares ( 3.0 acres) of urban land.

Given that $80.7 \%$ of the U.S. population lives in urban areas and a 2019 U.S. population of 328.2 million people, approximately 265 million people live in U.S. urban areas. Planting 23 million trees per year equates to each urban resident planting one tree every 11.5 years. As the average person lives 78.5 years, each urban resident would need to plant about seven trees during their lifetime to sustain tree cover in existing urban areas.

In the future, climate change could affect carbon storage and sequestration rates, but there are various counter-indications as to what might happen to carbon storage and sequestration. While climate change effects of increased $\mathrm{CO}_{2}$ and longer growing seasons will increase growth rates (e.g., Taub 2010, Deryng et al. 2016) and potentially stand densities (Devi et al. 2020), decreasing wood densities (Pretzsch et al. 2018) and possible decreased life spans due to increased growth rates when young (Büntgen et al. 2019) may offset carbon gains of increased growth. Given the uncertainties of future carbon densities per $\mathrm{m}^{2}$ of tree cover, projections of urban forest carbon effects use current carbon storage and sequestration densities.

### 3.2.1. Carbon Storage and Value

Carbon storage values are related to tree species, sizes and densities, while annual carbon sequestration relates these same factors plus annual growth and mortality rates. Carbon storage is estimated based on the national average carbon storage density ( $\mathrm{kgC} / \mathrm{m}^{2}$ tree cover) from several U.S. cities. Gross carbon sequestration ( $\mathrm{kgC} / \mathrm{m}^{2}$ tree cover $/ \mathrm{yr}$ ) is based on state specific growth rates and average tree competition and conditions as derived from the sample of U.S. cities. Net sequestration accounts for carbon losses due to mortality and tree decomposition and are estimated as $74 \%$ of gross sequestration (Nowak et al. 2013).

Carbon storage in existing U.S. urban forests is projected to decrease by 180 million tonnes ( $-21 \%$ ) by 2060, declining from 852 million tonnes (2010) to 671 million tonnes (2060) (Table 2). Given the 2020 value of the social cost of carbon ( $\$ 188 / \mathrm{tC}$ in 2018 dollars; Interagency Working Group on Social Cost of Carbon 2016), the carbon storage value of the urban forest will decrease by $\$ 34$ billion by 2060 , declining from $\$ 160$ billion (2010) to $\$ 126$ billion (2060). If tree cover is enhanced by $10 \%$, carbon storage could increase to 937 million tonnes ( $\$ 176$ billion).

Table 2. Amounts and differences (million tonnes) in 2060 carbon storage and annual carbon sequestration (seq.) based on current projected trends, canopy conservation and canopy enhancement scenarios.

| Scenario | Storage | Diffa | Seq. | Diffa $^{\text {a }}$ |
| :--- | :---: | :---: | :---: | :---: |
| Trend | 671.4 | na | 26.6 | na |
| Conserve | 851.9 | 180.5 | 34.0 | 7.4 |
| Enhance | 937.1 | 265.7 | 37.4 | 10.8 |

a difference from trend scenario
na - not applicable

States with the greatest increase in carbon storage and sequestration due to the conservation or enhancement of current percent tree cover are Florida, Georgia and Texas (Tables 3-4). Counties that have the greatest increases in carbon storage and sequestration from canopy conservation or enhancement tend to be in Texas, Arizona, Georgia and Florida (Tables 5-6).

Table 3. Differences in 2060 state carbon storage (tonnes) for conserve canopy and enhance canopy scenarios vs. the current trend scenario.

### 3.2.2. Building Energy Conservation

Building energy conservation values are related to average tree distributions around buildings among land cover classes and changes in land cover distribution and tree cover with land cover classes (Nowak et al. 2017). The values are also related to state-specific energy costs and types of energy used to heat and cool buildings, as well as regionally specific tree cover effects on building energy use depending on tree size and orientation around a building. On average, urban trees reduce building energy use by 7.2\% (Nowak and Greenfield 2017).

Projections of tree effects on building energy use assume that energy costs and fuel types stay consistent in the future (2030 and 2060). In reality, energy types and distributions will likely change in the future as energy efficiencies and building designs change. Energy costs are also likely to increase in the coming years.

Energy conservation in existing U.S. urban forests is projected to decrease by $\$ 855$ million by 2060 , declining from $\$ 4.1$ billion (2010) to $\$ 3.3$ billion (2060). Conserving tree cover at its current percent tree cover would save an additional $\$ 855$ million in energy costs in 2060; enhancing urban tree cover by 2060 would save an additional $\$ 1.3$ billion per year (Table 7 ).

Table 7. Amounts and differences (million \$) in 2060 energy savings based on current projected trends, canopy conservation and canopy enhancement scenarios.

| Scenario | Energy Savings (\$) | Diff $^{\text {a }}$ |
| :--- | :---: | :---: |
| Trend | 3,278 | na |
| Conserve | 4,132 | 855 |
| Enhance | 4,545 | 1,268 |

a difference from trend scenario
na - not applicable

States with the greatest increase in energy savings due to the conservation or enhancement of current percent tree cover are Florida, Texas and Massachusetts (Table 8). Counties that have the greatest energy savings from canopy conservation or enhancement tend to be from the same states (Table 9).

### 3.2.3. Avoided Emissions

The projected changes in building energy use will alter emissions from the sources of fuels used to produce the energy. State or national emission factors and costs by fuel type were used to estimate changes in emissions due to changes in building energy use (Nowak et al. 2017). The emission factors and costs from 2010 were held constant for the year 2060.

Avoided pollutant emissions in existing U.S. urban areas is projected to decrease by $\$ 318$ million by 2060, declining from $\$ 1.4$ billion (2010) to $\$ 1.1$ billion (2060). Relative to the current declining tree cover projection, conserving tree cover at its current percent tree cover would avoid the emission of an additional 1.4 million tonnes of carbon by 2060 and avoid pollutant emissions $\left(\mathrm{CO}_{2}, \mathrm{NO}_{\mathrm{x}}, \mathrm{SO}_{2}, \mathrm{CO}\right.$, $\mathrm{CH}_{4}$, VOCs, $\mathrm{PM}_{10}$ and $\mathrm{PM}_{2.5}$ ) with an associated value of $\$ 318$ million per year. Enhancing urban tree cover by 2060 would avoid the emission of an additional 2.0 million tonnes of carbon by 2060, and avoid pollutant emissions with an associated value of $\$ 462$ million per year (Table 10).

Table 10. Amounts and differences in 2060 avoided annual carbon emissions and total value from reduced annual pollutant emissions based on current projected trends, canopy conservation and canopy enhancement scenarios.

| Scenario | Carbon $^{\mathrm{a}}$ | Diff $^{\mathrm{b}}$ | Emission $^{\text {c }}$ | Diff $^{\mathrm{b}}$ |

States with the greatest increase in 2060 in avoided carbon and pollutant emissions due to the conservation or enhancement of current percent tree cover are Ohio, Texas and Florida (Tables 1112). Counties that have the greatest increase in avoided carbon and pollutant emissions from canopy conservation or enhancement are Maricopa, Ariz.; Harris, Texas; and Cook, Ill. (Tables 13-14).
